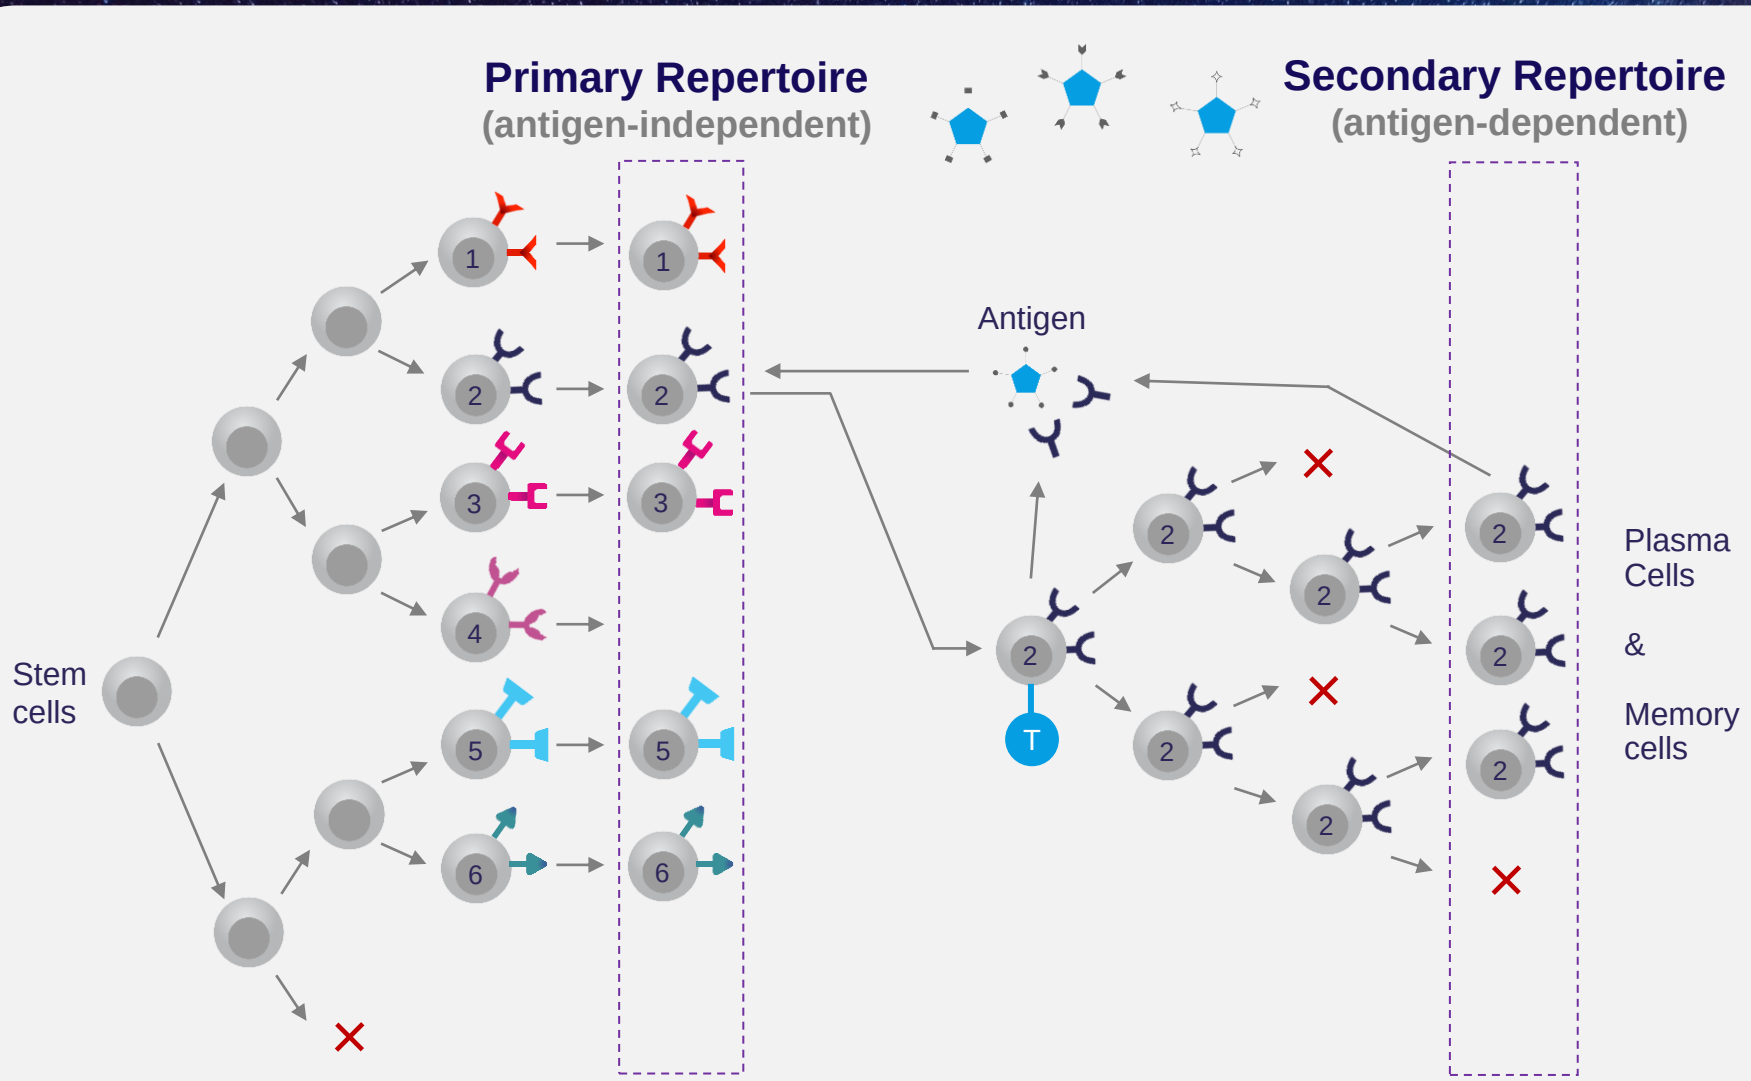
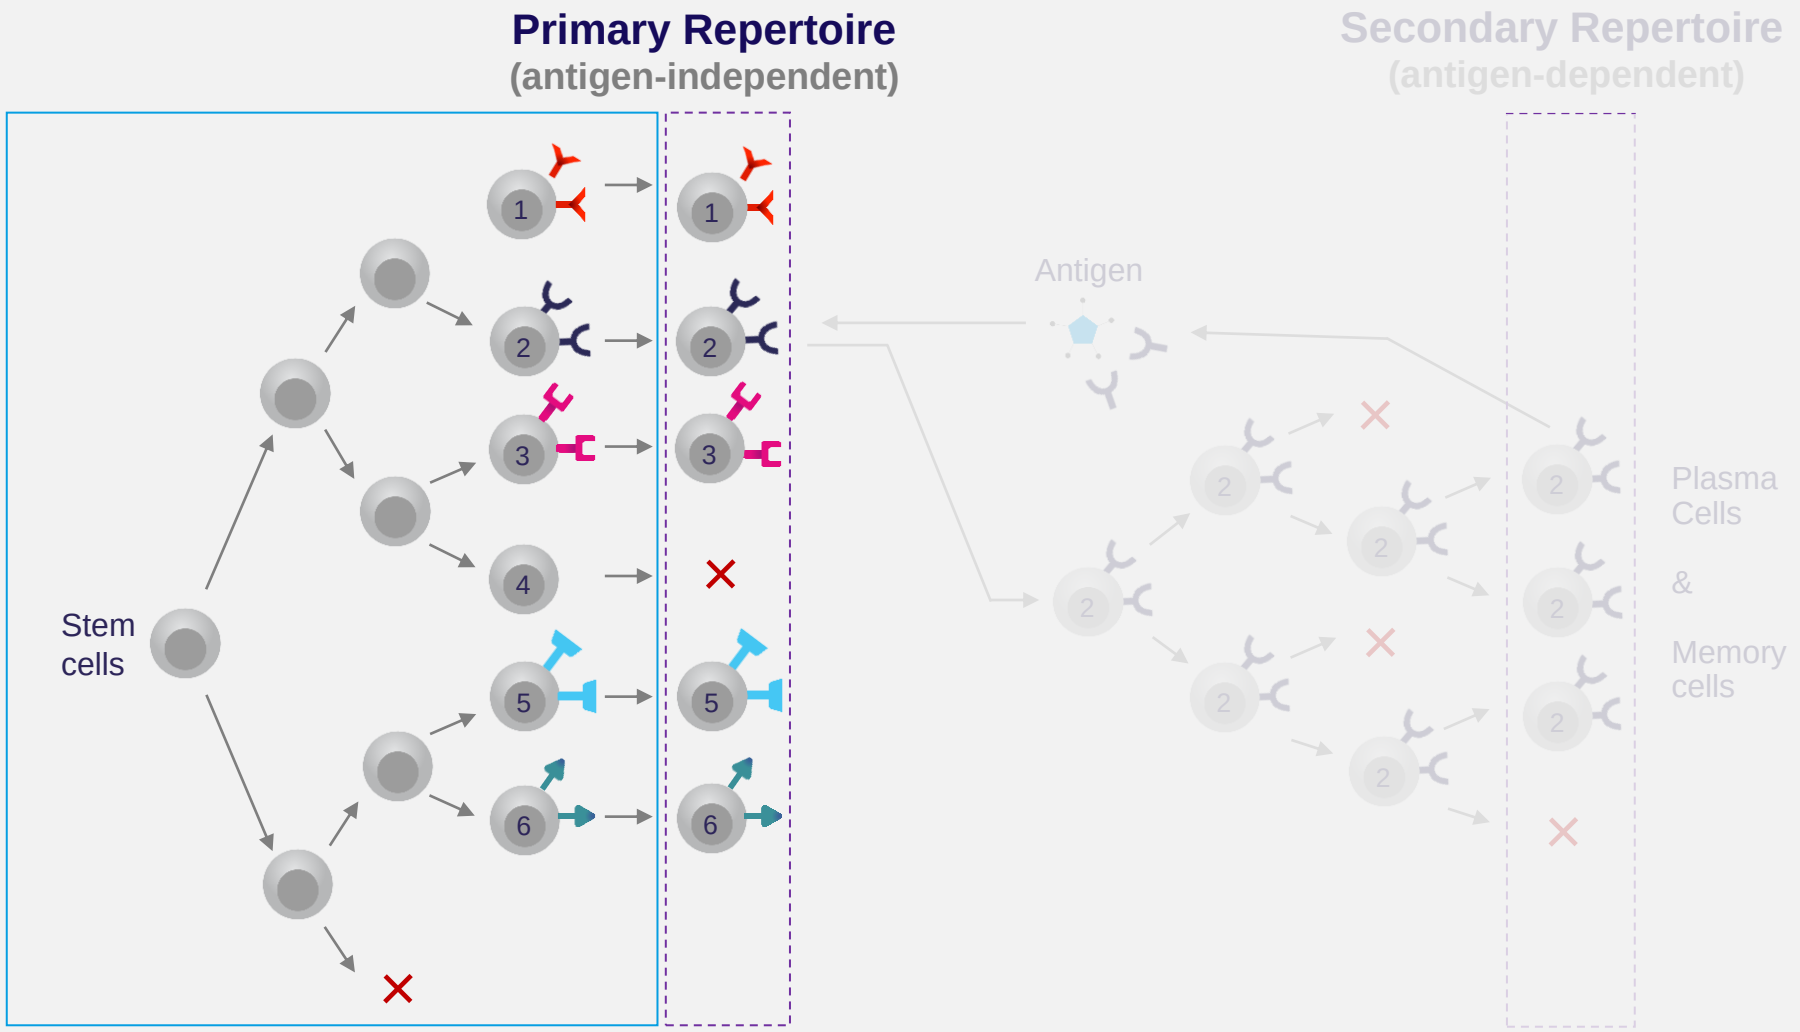
THE B CELL RECEPTOR (ANTIBODY) REPERTOIRE

"The sum of all B cells expressing distinct B cell receptors, necessary to bind diverse antigens and produce an effective humoral immune response"

THE B CELL RECEPTOR REPERTOIRE HAD TWO ELEMENTS



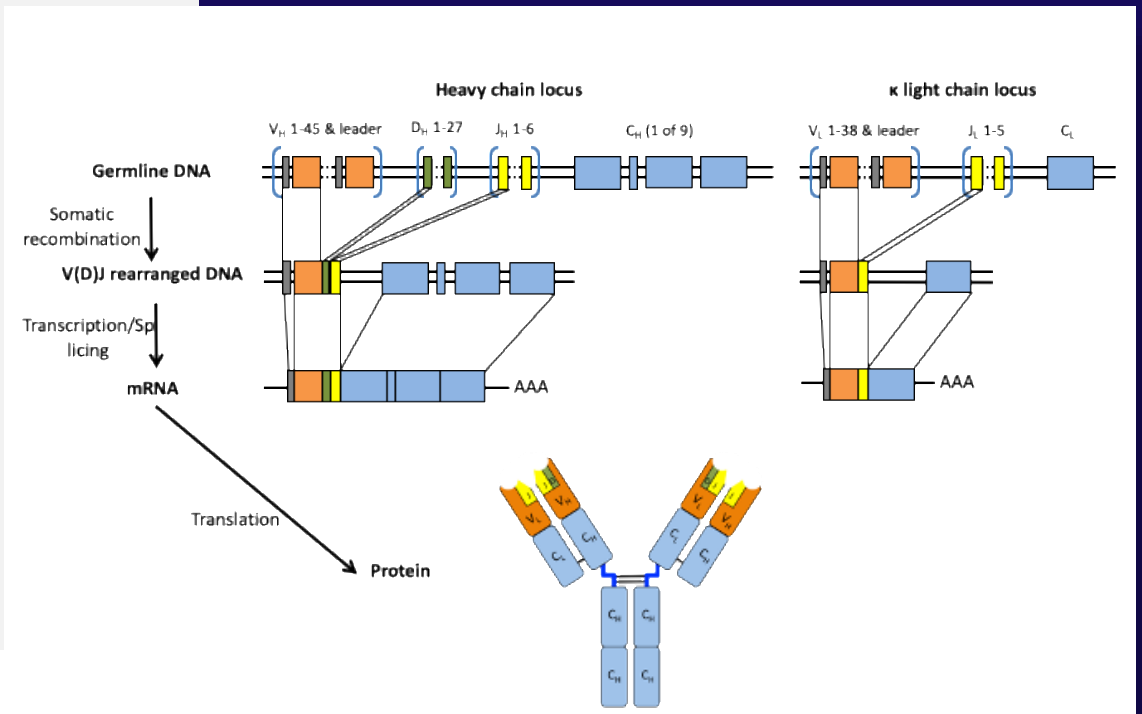
FORMING THE PRIMARY REPERTOIRE



COMBINATORIAL DIVERSITY – VDJ RECOMBINATION

Somatic recombination of gene segments during B cell development

Element	Immunoglobulin	
	H	K+ λ
Variable segments (V)	~40	~70
Diversity segment (D)	23	0
D segments read in three frames	rarely	-
Joining segments (J)	6	5(κ) 4(λ)
Joints with N- and P-nucleotides	2	50% of joints
Number of V gene pairs	1.9×10^6	
Junctional diversity	$\sim 3 \times 10^7$	
Total diversity	$\sim 5 \times 10^{13}$	



FORMING THE SECONDARY REPERTOIRE

High-Throughput Sequencing of the Zebrafish Antibody Repertoire

Joshua A. Weinstein,[1]* Ning Jiang,[2]* Richard A. White III,[3]
Daniel S. Fisher,[1,4,5] Stephen R. Quake[1,2,3,4]†

Despite tremendous progress in understanding the nature of the immune system, the full diversity of an organism's antibody repertoire is unknown. We used high-throughput sequencing of the variable domain of the antibody heavy chain from 14 zebrafish to analyze VDJ usage and antibody sequence. Zebrafish were found to use between 50 and 86% of all possible VDJ combinations and shared a similar frequency distribution, with some correlation of VDJ patterns between individuals. Zebrafish antibodies retained a few thousand unique heavy chains that also exhibited a shared frequency distribution. We found evidence of convergence, in which different individuals made the same antibody. This approach provides insight into the breadth of the expressed antibody repertoire and immunological diversity at the level of an individual organism.

The nature of the immune system's antibody repertoire has been a subject of fascination for more than a century. This repertoire is highly plastic and can be directed to create antibodies with broad chemical diversity and high selectivity (*1*, *2*). There is also a good understanding of the potential diversity available and the mechanistic aspects of how this diversity is generated. Antibodies are composed of two types of chains (heavy and light), each containing a highly diversified antigen-binding domain (variable). The V, D, and J gene segments of the antibody heavy-chain variable genes go through a series of recombination events to generate a new heavy-chain gene (Fig. 1). Antibodies are formed by a mixture of recombination among gene segments, sequence diversification at the junctions of these segments, and point mutations throughout the gene (*3*). Estimates of immune diversity for antibodies or the related T cell receptors either have attempted to extrapolate from small samples to entire systems or have been limited by coarse resolution of immune receptor genes (*4*). However, certain very elementary questions have remained open more than a half-century after being posed (*1*, *5*, *6*): It is still unclear what fraction of the potential repertoire is expressed in an individual at any point in time and how similar repertoires are between individuals who have lived in similar environments. Moreover, because each individual's immune system is an independent experiment in evolution by natural selection, these questions about repertoire similarity also inform our understanding of evolutionary diversity and convergence.

Zebrafish are an ideal model system for studying the adaptive immune system because in evolutionary terms they have the earliest recognizable adaptive immune system whose features match the essential human elements (*7*, *8*). Like humans, zebrafish have a recombination activating gene (RAG) and a combinatorial rearrangement of V, D, and J gene segments to create antibodies. They also have junctional diversity during recombination and somatic hypermutation of antibodies to improve specificity, and the organization of their immunoglobulin (Ig) gene loci approximates that of human (*9*). In addition, the zebrafish immune system has only ~300,000 antibody-producing B cells, making it three orders of magnitude simpler than mouse and five orders simpler than human in this regard.

We developed an approach to characterize the antibody repertoire of zebrafish by analyzing complimentarity-determining region 3 (CDR3) of the heavy chain, which contains the vast majority of immunoglobulin diversity (*10*, *11*) and can be captured in a single sequencing read (Fig. 1). Using the 454 GS FLX high-throughput pyrosequencing technology allowed sequencing of 640 million bases of zebrafish antibody cDNA from 14 zebrafish in four families (Fig. 1B). Zebrafish were raised in separate aquaria for each family and were allowed to have normal interactions with the environment, including the development of natural internal flora. We chose to investigate the quiescent state of the immune system, a state where the zebrafish had sampled a complex but fairly innocuous environment and had established an equilibrium of normal immune function. mRNA was prepared from whole fish, and we synthesized cDNA using primers designed to capture the entire variable region.

Between 28,000 and 112,000 useful sequencing reads were obtained per fish, and we focused our analysis on CDR3 sequences. Each read was assigned V and J by alignment to a reference with a 99.6% success rate (table S3); failures were due to similarity in some of the V gene segments. D was determined for each read by applying a clustering algorithm to all of the reads within a given

HOW RARE IS CONVERGENCE?

DIVERSITY OF THE HUMAN REPERTOIRE IS THEORETICALLY 1 X 10^{13}

- Number of peripheral B cells in a healthy individual is approx. $1x10^9$
- Circulating B Cell Repertoire is therefore a fraction of the total diversity
- The amount of information encoded in “genome” of the adaptive immune system exceeds the human genome by 4 orders of magnitude

10 INDIVIDUALS VH SEQUENCED

3 BILLION HEAVY CHAINs

Briney *et al Nature 2019*

- Largely unique repertoires for each individual
- Between 2 individuals 0.95% of the repertoire was shared. Shared clonotypes were skewed towards short CDR3s
- Only 0.022% of clones were shared between all 10 individuals
- Commonality is driven by early BCR development rather than common antigen-specific selection, although there is some convergence due to vaccination and common infections

CONVERGENCE INCREASES AFTER COMMON ANTIGEN EXPOSURE

- Convergence increases after a **common** antigen stimulus and can be used to identify rare antigen-specific sequences
- Vaccination used as an example of a strong, specific stimulus

Identification of Antigen-Specific B Cell Receptor Sequences Using Public Repertoire Analysis

AUTOANTIBODIES ARE GENERALLY VIEWED AS ‘BAD GUYS”

MANY AUTOIMMUNE DISEASES ARE THE RESULT OF PATHOGENIC AUTOANTIBODIES:

- SLE (Polyclonal autoreactive B cells)
- Myasthenia Gravis (anti-AchR)
- Neurological disease (anti-NMDA Receptor encephalitis
- Pemphigus (anti- desmosomal proteins)

TREATMENTS:

- Ablate B cells (anti-CD20)
- Plasmapheresis
- Anti-FcRn
- High dose IVIG to block
- Anti-IDs (e.g. anti-anti-Dsg3 autoantibodies)

IF THERE ARE BAD GUYS THERE ARE ALWAYS GOOD GUYS

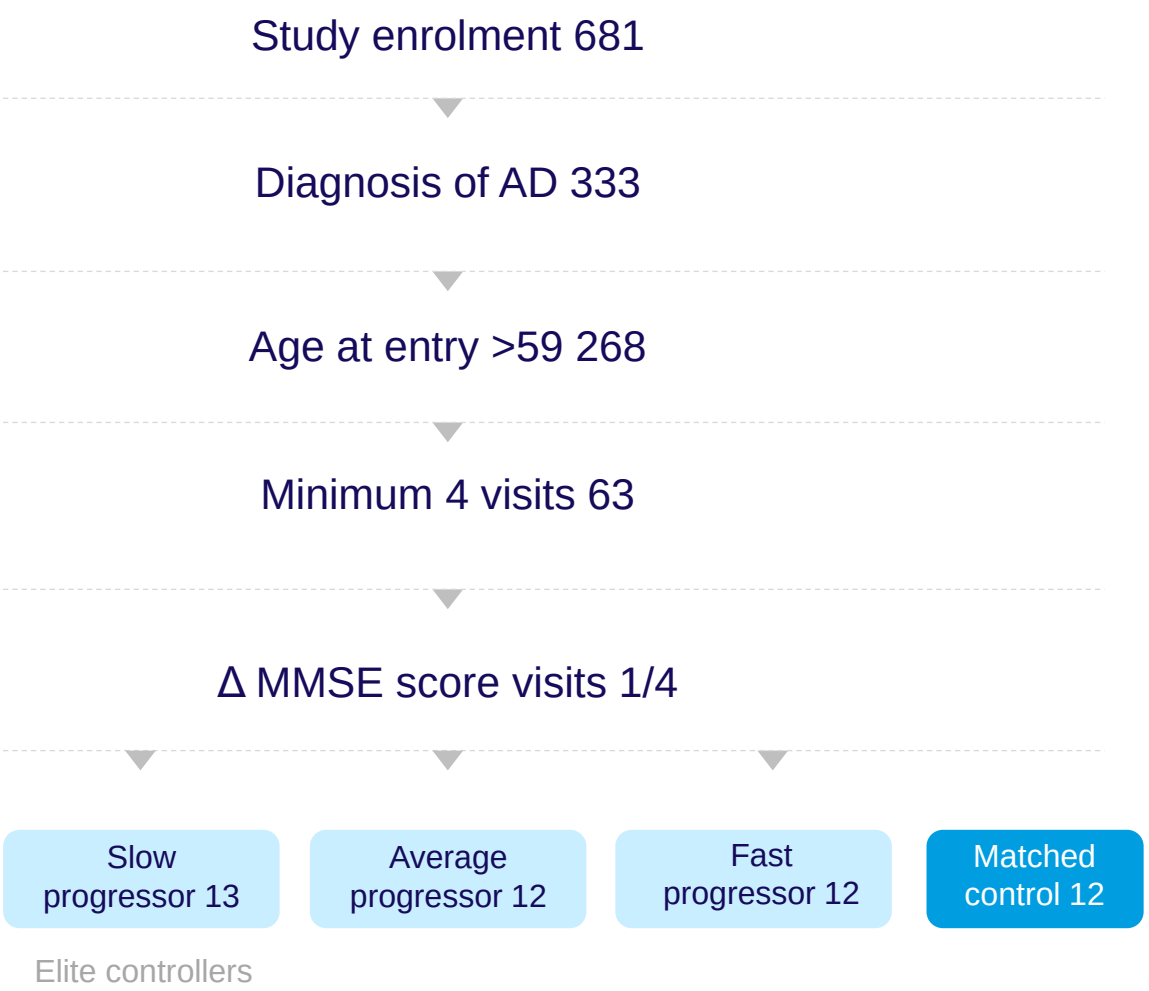
Mini Mental State Exam score used for assessment of disease progression

Starting range 15-24 out of a maximum score of 30



IDENTIFICATION OF AD CONVERGENT CLONES

Sequence data from 30 Alzheimer's patients was triaged to select 38 antibodies according to the following workflow:

- **CLONOTYPING**:
  sequences with near identical V, J, and CDR3 length are clustered
- **EXCLUSIVITY:**
  Clonotypes chosen which are sare exclusive to resilient group and not seen in healthy controls
- **EXPRESSION FILTER:**
  Sequence seen more than once per sample
- **MUTATION FILTER:**
  Filter for clonotypes undergoing active selection via somatic hypermutation

Exclusively convergent clonotypes have a highly skewed VH germline gene distribution which indicates disease specific activation
